ABSTRACT

The modified Rodnan skin score (mRSS) is a measure of skin thickness and is used as a primary or secondary outcome measure in clinical trials of systemic sclerosis (scleroderma). This state-of-art review provides a historical perspective of the development of the mRSS, summarizes the performance of mRSS as an outcome measure, provides guidance on assessing mRSS, and makes recommendations for incorporation of the mRSS into clinical trials.

Keywords: Clinical trials, Modified Rodnan skin score, Skin thickness, Standardization

Introduction

The modified Rodnan skin score (mRSS) is a measure of skin thickness and is used as a primary or secondary outcome measure in clinical trials of systemic sclerosis (SSc, scleroderma). This article gives a brief history of the development of the mRSS, outlines practical aspects of assessing mRSS in clinical trials, and provides recommendations for the use of the mRSS in phase 2 and 3 clinical trials where change in skin thickness is the primary or secondary outcome measure. This document highlights the views of scleroderma experts and is not meant to be used as a regulatory document.

Natural history of skin involvement in SSc

SSc is sub-classified into diffuse cutaneous SSc (dcSSc) or limited cutaneous SSc (lcSSc) based on the extent of skin involvement. lcSSc is defined as skin thickening distal to the elbows and knees, with or without involvement of the face. dcSSc is characterized by the presence of skin thickening, proximal as well as distal, to the elbows and knees with or without involvement of the face (1). It is generally accepted that skin thickness tends to increase in early dcSSc and decrease in late dcSSc, although the time of peak involvement is typically 12-18 months after the onset of skin thickening. “Early” dcSSc is often defined as the period of rapidly increasing induration (“thickening”) of the skin. Although there is substantial individual heterogeneity, skin involvement in dcSSc may go through 3 phases: (i) an edematous phase that usually lasts 6-12 months; (ii) a fibrotic or
indurative phase that lasts from 1-4 years or longer; and (iii) an atrophic phase that lasts for rest of the patient’s life, although rarely patients have a recurrence of progressive skin involvement in later disease (Fig. 1). The duration of each phase may differ in each individual patient and the phases often overlap each other. The course of skin thickness also differs by serum autoantibodies – patients with anti-RNA polymerase-III tend to have more rapid progression than do those with anti-Scl-70 (topoisomerase I) antibody. In lcSSc, there is little change in skin thickness over time except in the subset who are anti-Scl-70 positive and progress to dcSSc over time (2).

Skin thickness as surrogate of disease severity and mortality

Measurement of skin thickness is used as a surrogate for disease activity, severity and mortality in patients with dcSSc. In early dcSSc, an increase in skin thickening is generally associated with new or worsening internal organ involvement and increased mortality (3, 4). Worsening mRSS is associated with higher mortality, and both negative renal and cardiac outcomes (5). Internal organ involvement or worsening are particularly associated with the prior trajectory of skin thickening (3), and higher skin thickness progression rates are predictive of internal organ involvement and mortality (6). In addition, patients who never achieved a high skin score have a lower frequency of major organ-based complications, and those with high skin scores that failed to improve by 3 years of disease have significantly higher mortality. Conversely, attenuation of peak skin score or improvement is associated with favorable outcomes, including better survival (5, 7). These points emphasize the potential benefit of including milder or early cases of SSc in clinical trials (8, 9).

Historical perspective

Dr. Gerald Rodnan at the University of Pittsburgh, theorized about, and then studied, the trajectory of skin thickening in the course of SSc. He noted that the skin, particularly the dermis, thickened initially and after some years usually thinned. He became convinced that an observer could, with practice, accurately estimate how thick skin is by palpating it. To substantiate his point, he developed a method for estimating thickness by clinical palpation using a 0-4 scale. He performed an experiment in which he estimated skin thickness of the distal forearm by skin palpation in patients with SSc and then performed a skin punch biopsy in that same location. He then weighed the plug of skin from the biopsy. The correlation between his clinical estimate of thickness and the weight of a 7-mm punch biopsy plug was 0.81 (10). He further explored clinical palpation for estimating skin thickness in 26 cutaneous sites. The first full description of his methodology was published in 1982 in the context of a controlled study of D-penicillamine in SSc (11).

Some years later, Dr. Rodnan’s colleagues modified his method by estimating skin thickness using a 0-3 scale in 17 body areas (Fig. 2). Nine of the original areas (neck [1], shoulders [2], breasts [2], upper back [1], lower back [1], toes [2]) were dropped because clinical investigators found it too difficult to come to consensus due to high inter-observer variation. One of the first applications of this mRSS (12) was in a randomized clinical trial (RCT) of high-dose versus low-dose D-penicillamine in early dcSSc (12, 13).

During the same period, when the mRSS was developed, several groups were exploring different ways of assessing global skin involvement in patients with SSc. For example, Kahaleh et al (14) proposed a modification of the Rodnan technique for measuring skin thickness (scores ranged from 0-66). Investigators at UCLA developed a skin scoring technique which involved assessment of skin teth-erining or hide binding in 10 body areas (scores ranged from 0-30) (15). Another method assessed the percentage of total body surface area affected by scleroderma (16). However, consensus was eventually reached where the mRSS became the gold standard for measuring skin thickness in SSc (17).

The modified Rodnan Skin Score as an outcome measure

The mRSS meets the OMERACT filters of truth, discrimination, and feasibility, as detailed in Merkel et al (18). Briefly, mRSS has the following characteristics:

Printed Name: ____________________________
Signature: ____________________________ Date: __________

a. **Feasible:** Easy to perform with no equipment and requires little time
b. **Face validity:** Captures and measures skin thickness
c. **Content validity:** Covers the affected body areas in SSc
d. **Construct validity:** Correlates with other measures of SSc such as durometer (19, 20) and ultrasound (21)
e. **Criterion validity:** Reflects the gold standard of skin biopsy (22). The correlation between clinical estimate of thickness by Dr. Rodnan and the weight of a 7-mm punch biopsy plug was 0.81 (10). In addition, myo-fibroblast and hyalinized collagen scores on the skin biopsy correlated with the forearm mRSS score in a single-center study (correlation coefficients of 0.83 and 0.78, respectively) (23)
f. **Sensitivity to change:** Analysis of multicenter clinical trials show change over time. For example, the mRSS was able to differentiate between treatment with methotrexate and placebo in early dcSSc and between cyclophosphamide and placebo in the dcSSc subset in the Scleroderma Lung Study-I (24). The mRSS also improved in the Autologous Stem Cell Transplant Study (25) and showed a trend towards improvement with treatment with tocilizumab (26). In addition, the minimal clinically important difference of the mRSS has been established in dcSSc and ranges between 3.5 to 5.3 units in the D-penicillamine study (the mean baseline mRSS was 21 units) (27). The minimal clinically important difference estimates differ by the baseline mRSS and may be lower for recent trials that are recruiting milder skin thickening in dcSSc (27).

Utilizing the mRSS in clinical trials and routine care of SSc

**Practical aspects**

**Positioning of the patient**

This is an important part of assessing mRSS. Each area examined should be in the relaxed position so the underlying muscles are relaxed to avoid falsely overestimating the area skin scores. Proper scoring cannot be done with patients in regular clothes. An examination gown or loose clothing is needed with appropriate use of sheet/drape. When evaluating the upper extremities, face, and anterior chest, we recommend the patient be seated in a relaxed position with arms by the side of the body. When evaluating the abdomen and lower extremities, we recommend the patient lie supine on an examination table or bed with the hips at 45 degrees’ flexion and feet are dorsiflexed.

**Assessing skin thickness**

There are two techniques to accomplish this by palpation of the skin (Fig. 3A).

I. Use an index finger and thumb where the skin is rolled or pinched gently to gauge thickness.
II. Use two thumbs to form a fold of skin between advancing lateral thumb borders. This method may be easier when skin overlies bone such as in the fingers and on the dorsum of the hands.

Fig. 2 - Modified Rodnan skin score (mRSS) is assessed in 17 different areas. Case report form to capture mRSS. (To download this form, please see the Supplementary material to this article, available online at www.sclerodermajournal.com).
It is important to understand the relative distribution of subcutaneous fat and underlying musculoskeletal structures in different anatomical areas as they may alter the examiner’s appreciation of skin thickness.

Skin should be scored based on how it feels and not how it looks. For example, shiny skin or abnormally pigmented skin does not imply increased thickness.

**Global average vs. maximum score vs. most representative area of an anatomic area**

There are differences in scoring mRSS in clinical practice but we recommend standardizing mRSS measurement in clinical trials. The three commonly used techniques include:

**Maximum score:** The examiner assigns a score to individual anatomic areas according to the most severe local involvement. For example, if the distal forearm has a patch considered 2 whereas the remainder of the forearm is 1, then a score of 2 is recorded.

**Representative area:** The examiner scores individual areas with a score that is most representative of the area. In the example above, 1 would be the most representative score.

**Global average:** The examiner scores individual areas and takes average of the area. In the example above, 1 would be
the most representative score. However, if the distal forearm had areas scored 2 and 3 whereas the majority of the forearm is 1, the average would be 2 (differs from representative area where the score would be 1). Some investigators prefer not to divide the scored region formally into subareas but prefer to provide an average score that reflects overall skin thickness and accounts for the observed variation in a more flexible fashion. Both methods are sound and acceptable.

We propose using either the “representative area” or “global average” method (Fig. 4). In addition, there is a theoretical disadvantage of using “maximum score” as it may limit sensitivity to change. Consider an area over the forearm [as an example] that remains a 3 but the other forearm areas improve. Using maximum score, the forearm will continue to be scored as 3 despite definite improvement. One point of clarification is that if an area of skin has 1 but no more severe thickening, then the score of 1 is given; i.e., for global average, maximizing applies in this situation.

**Scoring of each individual cutaneous area (Figs. 3A-3D)**

- mRSS = 0 is “normal skin” where the examiner appreciates fine wrinkles but no skin thickness is present.
- mRSS = 1 is defined as definite but “mild” skin thickness where the examiner can easily make skin folds between two fingers; fine wrinkles are acceptable.
- mRSS = 2 is defined as “moderate” skin thickness with difficulty in making skin folds and no wrinkles.
- mRSS = 3 is defined as “severe” skin thickness with inability to make skin folds between two examining fingers.

**The same examiner should evaluate the skin thickness throughout the trial**

Each outcome measure inherently has measurement variability. It is recommended that the same assessor examine the patient for the duration of the trial. The inter-observer variability of the mRSS is 4.6 units (coefficient of variation = 25%) and the intra-observer variability is 2.5 units (coefficient of variation = 12%) (12), with these variabilities better than that of measuring swollen and tender joint counts in rheumatoid arthritis, both part of the standard assessment in that disease (28). Others have found similar results for the variability of the mRSS (29).

Teaching reduces variability of mRSS

The mRSS is a validated outcome in dcSSc but, as in rheumatoid arthritis, training assessors reduce variability. In a 12-investigator SSc teaching course, the intraclass correlation co-efficient (ICC) was 0.639, an acceptable reliability. On repeat training 7 months later, the ICC was 0.684, essentially the same. These data indicate that repeated retraining over time is not necessary (at least over 7 months). However, inter-investigator variability was high at both training sessions (standard deviation: 3.5-5.3) emphasizing that the intra-person reproducibility of the mRSS is much higher than between examiners; highlighting the need to have the same investigator consistently measuring the same patient (30).

Additional unpublished data come from an investigator meeting where training was conducted as part of a phase 2 clinical trial in dcSSc. Fourteen investigators were asked to perform mRSS on two subjects with dcSSc. Immediately after the completion of mRSS, each investigator viewed a video demonstration by an expert examining a subject exhibiting different aspects of skin scoring, followed by a live demonstration by an expert on one subject with SSc on standardization of mRSS in clinical trials. Then, the investigators examined the same two subjects again and recorded their mRSS. Using a linear mixed model with random effects for both subjects and physicians, the results indicated that the video demonstration led to a decrease in the investigator variability (standard deviation decreased from 3.7 units before training to 1.6 units after training, a decrease of 56%), while the variability in mRSS attributable to variability among patients decreased less noticeably after training (2.5 units to 2.0 units after training). The latter is expected as the variability in mRSS captures the inherent heterogeneity in mRSS that exist across subjects.

Caveats in mRSS measurement

1. The edematous phase of dcSSc is usually associated with non-pitting edema of the skin. The mRSS may be difficult to assess during the edematous phase of SSC and mRSS has been shown to be inaccurate in this setting, with a correlation between an edema score on physical examination and edema on biopsy of 0.069-0.169 (22). There is no agreement upon the approach for determining thickness when skin has edema. ‘Puffiness’ of the skin, generally fingers, is scored as 0.
II. Tethering or hide binding is defined as strong attachment of the lower dermis to the underlying subcutaneous tissues, making skin movement difficult even in the absence of skin thickening. Although tethering can occur in the fibrotic phase of the disease, it is also associated with atrophic or “thin” skin. The mRSS does not score tethering.

III. Atrophic skin should be given a mRSS of 0, although this is erroneously scored as 3 due to underlying tethering.

Other aspects

Assessment in pediatric population: In healthy children, the texture of the skin shows age-appropriate skin thickness due to increased subcutaneous fat tissue compared to adults and correlates with the body mass index (BMI) and the Tanner stage (31). In healthy children, skin is often appreciated as thicker due to increased subcutaneous fat. The latter is correlated with BMI and Tanner stage and decreases with age and sexual maturation. mRSS is not yet validated in juvenile SSc but there are ongoing international efforts to accomplish this. Therefore, the mRSS assessment should be performed in specialized pediatric scleroderma centers and should be corrected for BMI and Tanner stages.

Ethnicity differences: There are significant differences in mRSS in different ethnic groups in dcSSc patients. Japanese patients have lower mRSS in US and UK cohorts, although there is no study comparing mRSS by the same examiners in different populations. These differences could be explained, in part, by different distribution of SSc-related serum auto-antibodies among ethnic groups; i.e., a higher proportion of anti-RNA polymerase III antibody in US and UK populations, compared with Japanese patients (32).

Measurement in limited cutaneous SSc: The mRSS can be assessed in lcSSc, but in this population, it is not a surrogate of disease severity or mortality and is generally not sensitive to change (likely due to a ceiling effect).

Recommendations for assessing mRSS in clinical trials

Phase 3 trial focused on mRSS as the primary outcome measure or a key secondary outcome measure

Training is strongly encouraged for standardization of mRSS in any clinical trial of SSc. Each assessor who will be performing mRSS in the trial should undergo training. It should be highlighted that the same assessor should perform mRSS during the course of the trial. We recommend 2 phases for training and this is based on successful training conducted during the phase 2 trial (discussed above in the section “Teaching reduces variability of mRSS”) and in an ongoing phase 3 trial.

Teaching phase: This should be accomplished by a video demonstration (by an expert examining a patient with SSC demonstrating different aspects of skin scoring) followed by a live demonstration by an expert on one or more patients with SSC.

Evaluation phase: Each trainee examines at least three patients with SSC. These patients should be different than the training patients, and should preferably reflect the inclusion criteria for the proposed trial.

Certification (Fig. 5): Due to logistical issues (requirements of patients and costs associated with live training), it may be appropriate to accept the certification for other trials if the assessor has undergone live training, passed the evaluation phase, and has performed the mRSS in an ongoing or recent trial within the last two years. This assumes that the assessor is currently performing mRSS in an ongoing trial or has done so in the recent past. In addition, regular evaluation should be conducted during the course of a trial to assess intra-rater reliability. Otherwise, they are encouraged to undergo recertification.

Phase 3 trial where mRSS is a secondary outcome measure or a phase 2 trial focused on mRSS as the primary outcome measure or key secondary outcome measure

We encourage use the aforementioned plan for standardization of the mRSS, but we acknowledge the costs associated with training each assessor. In lieu of a formal training session, training at an investigator meeting could include a mRSS training video and live demonstration on a minimum of one SSc patient. Trainees should be given enough time for clarifications. Each trainee should receive a certificate at the
end of investigator meeting, which should be part of the reg-
ulatory binder for the trial.
Finally, we recommend discussing the above-outlined gu-
dance with the regulatory agencies associated with a spe-
cific research trial or drug development program.

Other practical aspects in a clinical trial

How often to conduct the mRSS: Based on change in mRSS in the published clinical trials and extensive experi-
ence of the authors in clinical practice, mRSS usually does
not have clinically meaningful changes (≥4 points) in less
than 3 months. However, there may be pharmacological
targets where an earlier effect may be seen on mRSS. There-
fore, it is reasonable to assess mRSS at least every 3 months
in a clinical situation.
Assessor should avoid looking at prior mRSS scores and
avoid asking patients to judge change in skin score since the
previous visit to reduce bias.
In addition, patients should be asked to avoid application
of moisturizers or cosmetics on day of skin scoring.

Conclusion

In conclusion, we have provided recommendations for performance of mRSS and have highlighted some areas of uncertainty that can form the agenda for future research.

Disclosures

Financial support: This work was funded in part by the NIH/NIAMS K24 AR06312 grant.
